Abstract

We investigate the Big-Bang Nucleosynthesis constraints on neutrino mixing in the framework of the two four-neutrino schemes that are favored by the results of neutrino oscillation experiments. We discuss the implications of these constraints for terrestrial short and long-baseline neutrino oscillation experiments and we present some possibilities of testing them in these experiments. In particular, we show that from the Big-Bang Nucleosynthesis constraints it follows that the $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ transition is severely suppressed in short-baseline experiments, whereas its oscillation amplitude in long-baseline experiments is of order 1. We also propose a new parameterization of the four-neutrino mixing matrix U which is appropriate for the schemes under consideration.

I. INTRODUCTION

The problem of the masses and mixing of neutrinos (see Refs. [1–4]) is the first priority problem of neutrino physics. Many experiments searching for neutrino oscillations and neutrinoless double-beta decay and investigating the high-energy part of the tritium beta-spectrum are going on or are under preparation. At present, indications that neutrinos are massive and mixed have been found in solar neutrino experiments (Homestake [5], Kamiokande [6], GALLEX [7], SAGE [8] and Super-Kamiokande [9,10]), in atmospheric neutrino experiments (Kamiokande [11], IMB [12], Soudan [13] and Super-Kamiokande [14,10]) and in the LSND experiment [15]. From the analyses of the data of these experiments in terms of neutrino oscillations it follows that there are three different scales of neutrino mass-squared differences:

$$\Delta m_{\text{sun}}^2 \sim 10^{-5} \text{ eV}^2 \text{ (MSW)} \quad \text{or} \quad \Delta m_{\text{sun}}^2 \sim 10^{-10} \text{ eV}^2 \text{ (vac. osc.)} \quad [16,17], \quad (1.1)$$

$$\Delta m_{\text{atm}}^2 \sim 5 \times 10^{-3} \text{ eV}^2 \quad [18], \quad (1.2)$$

$$\Delta m_{\text{SBL}}^2 \sim 1 \text{ eV}^2 \quad [15], \quad (1.3)$$

where Δm_{SBL}^2 is the neutrino mass-squared difference relevant for short-baseline (SBL) experiments, whose allowed range is determined by the positive results of the LSND experiment. The two possibilities for Δm_{sun}^2 correspond, respectively, to the MSW [19] and to the vacuum oscillation solutions of the solar neutrino problem.

Thus, at least four light neutrinos with definite masses (with only three active flavor neutrinos, ν_e, ν_μ, ν_τ) must exist in nature in order to accommodate the results of all neutrino oscillation experiments. This means that there exists at least one non-interacting sterile neutrino [20–26]. In this case, a left-handed neutrino field $\nu_{\alpha L}$ ($\alpha = e, \mu, \tau, s$) is a mixture of the left-handed components ν_{kL} of the four fields of neutrinos with definite masses m_k ($k = 1, \dots, 4$):

$$\nu_{\alpha L} = \sum_{k=1}^4 U_{\alpha k} \nu_{kL} \quad (\alpha = e, \mu, \tau, s), \quad (1.4)$$

where U is the 4×4 unitary mixing matrix.

In Ref. [22] we considered the schemes with four massive neutrinos and we have shown that from six possible mass spectra of four massive neutrinos only the following two mass spectra with two pairs of close masses separated by a gap of about 1 eV (the “LSND gap”) are compatible with all existing data (see also Ref. [23]):

$$(A) \quad \underbrace{m_1 < m_2}_{\text{SBL}} \ll \underbrace{m_3 < m_4}_{\text{sun}} \quad \text{and} \quad (B) \quad \underbrace{m_1 < m_2}_{\text{sun}} \ll \underbrace{m_3 < m_4}_{\text{SBL}}. \quad (1.5)$$

In scheme A, $\Delta m_{\text{atm}}^2 \equiv m_2^2 - m_1^2$ and $\Delta m_{\text{sun}}^2 \equiv m_4^2 - m_3^2$ are the mass-squared differences relevant for atmospheric and solar neutrino oscillations, respectively, whereas in scheme B we have $\Delta m_{\text{sun}}^2 \equiv m_2^2 - m_1^2$ and $\Delta m_{\text{atm}}^2 \equiv m_4^2 - m_3^2$. In both schemes $\Delta m_{\text{SBL}}^2 \equiv m_4^2 - m_1^2$ is relevant for neutrino oscillations in short-baseline experiments.

In this paper we study the compatibility of these two schemes with an upper bound¹ $N_\nu \lesssim 3.9$ (see Ref. [27]) on the effective number N_ν of light neutrinos relevant in Big-Bang Nucleosynthesis (BBN) (see, for example, Ref. [28]). We derive the constraints on some elements of the neutrino mixing matrix U that follow from $N_\nu \lesssim 3.9$ (see also Ref. [23]) and we discuss some possibilities to check these constraints in future short-baseline (SBL) and long-baseline (LBL) neutrino oscillation experiments.

Let us notice that there was recently some discussion in the literature about the validity of the upper bound $N_\nu \lesssim 3.9$ (see Ref. [27]). This discussion was initiated by conflicting results of different measurements of the deuterium abundance in high-redshift hydrogen clouds [29,30]. The situation is not completely clarified, but there seems to exist now a strong case in favor of $N_\nu \lesssim 3.9$ [27].

Let us define the quantities

$$c_\alpha \equiv \sum_{k=1,2} |U_{\alpha k}|^2 \quad (\alpha = e, \mu, \tau, s). \quad (1.6)$$

Okada and Yasuda [23] have shown that the bound $N_\nu \lesssim 3.9$ implies stringent limits on c_s in scheme A and $1 - c_s$ in scheme B. This means that the solar neutrino deficit is explained by small angle MSW $\nu_e \rightarrow \nu_s$ transitions² and the atmospheric neutrino anomaly by $\nu_\mu \rightarrow \nu_\tau$ transitions³ (see Ref. [18]). In this paper we have reanalyzed the constraints on the parameter c_s that follow from BBN. We have obtained more stringent upper bounds on c_s in scheme A and $1 - c_s$ in scheme B than those presented in Ref. [23] and we have investigated the effects of these constraints for SBL and LBL neutrino oscillations, some of which can be tested in the near future.

The plan of the paper is as follows. In Section II we summarize the formalism of SBL neutrino oscillations in the schemes A and B (for more details see Refs. [21,22]). In Section III we investigate in detail the dependence of N_ν on c_s . From the BBN upper bound on N_ν we obtain upper bounds on c_s in scheme A and $1 - c_s$ in scheme B. In Sections IV and V we obtain various general relations between SBL and LBL oscillation amplitudes and c_s . These relations can be useful to check the BBN constraints and to test the hypothesis of existence of a sterile neutrino. In Section V we also introduce a new parameterization of the mixing matrix that is suitable for the schemes under consideration.

¹For $N_\nu \geq 4$ the schemes A and B are trivially compatible with BBN.

²The vacuum oscillation and the large angle MSW solutions of the solar neutrino problem are disfavored by the data in the case of $\nu_e \rightarrow \nu_s$ transitions (see Refs. [31,32,16]).

³This explanation of the atmospheric neutrino anomaly is consistent with the recent results of the first long-baseline reactor experiment CHOOZ [33] in which no indications in favor of $\bar{\nu}_e$ disappearance were found.

II. NEUTRINO OSCILLATIONS IN SBL EXPERIMENTS

In the schemes under consideration the probability of $\nu_\alpha \rightarrow \nu_\beta$ transitions ($\beta \neq \alpha$) and the survival probability of ν_α in SBL experiments are given by [21]

$$P_{\nu_\alpha \rightarrow \nu_\beta} = \frac{1}{2} A_{\alpha;\beta} \left(1 - \cos \frac{\Delta m_{\text{SBL}}^2 L}{2p} \right), \quad (2.1)$$

$$P_{\nu_\alpha \rightarrow \nu_\alpha} = 1 - \frac{1}{2} B_{\alpha;\alpha} \left(1 - \cos \frac{\Delta m_{\text{SBL}}^2 L}{2p} \right), \quad (2.2)$$

with the oscillation amplitudes

$$A_{\alpha;\beta} = 4 \left| \sum_i U_{\beta i} U_{\alpha i}^* \right|^2, \quad (2.3)$$

$$B_{\alpha;\alpha} = 4 \left(\sum_i |U_{\alpha i}|^2 \right) \left(1 - \sum_i |U_{\alpha i}|^2 \right), \quad (2.4)$$

where the index i runs over the values 1, 2 or 3, 4.

In the following, we will consider values of Δm_{SBL}^2 in the wide range

$$10^{-1} \text{ eV}^2 \leq \Delta m_{\text{SBL}}^2 \leq 10^3 \text{ eV}^2. \quad (2.5)$$

The direct comparison of the regions in the $A_{\mu;e} - \Delta m_{\text{SBL}}^2$ plane allowed at 90% CL by the results of the LSND experiments with the regions excluded at 90% CL by the results of other SBL experiments indicate a considerably smaller allowed range for Δm_{SBL}^2 :

$$0.27 \text{ eV}^2 \lesssim \Delta m_{\text{SBL}}^2 \lesssim 2.2 \text{ eV}^2. \quad (2.6)$$

The results of the combined analysis of the data of all SBL experiments presented in Ref. [34] show that the lower bound $\Delta m_{\text{SBL}}^2 \gtrsim 0.27 \text{ eV}^2$ is robust (if the LSND indication is correct), whereas values of Δm_{SBL}^2 larger than 2.2 eV^2 maybe are not excluded.

Taking into account the results of solar and atmospheric neutrino experiments, from the exclusion curves of SBL disappearance experiments at each possible value of Δm_{SBL}^2 we have [22]

$$c_e \leq a_e^0 \quad \text{and} \quad 1 - c_\mu \leq a_\mu^0 \quad \text{in scheme A}, \quad (2.7)$$

$$1 - c_e \leq a_e^0 \quad \text{and} \quad c_\mu \leq a_\mu^0 \quad \text{in scheme B}, \quad (2.8)$$

where

$$a_\alpha^0 \equiv \frac{1}{2} \left(1 - \sqrt{1 - B_{\alpha;\alpha}^0} \right) \quad (\alpha = e, \mu) \quad (2.9)$$

and $B_{\alpha;\alpha}^0$ is the upper bound for the amplitude $B_{\alpha;\alpha}$ that can be obtained from the exclusion plots of SBL reactor and accelerator disappearance experiments. From the 90% CL exclusion curves of the Bugey [35] $\bar{\nu}_e \rightarrow \bar{\nu}_e$ reactor experiment and of the CDHS [36] and CCFR [37] $\nu_\mu \rightarrow \nu_\mu$ accelerator experiments it follows that a_e^0 is small ($a_e^0 \lesssim 4 \times 10^{-2}$) for Δm_{SBL}^2 in the range (2.5) and $a_\mu^0 \lesssim 10^{-1}$ for $\Delta m_{\text{SBL}}^2 \gtrsim 0.5 \text{ eV}^2$ (see Fig. 1 of Ref. [38]).

III. BBN CONSTRAINTS ON 4-NEUTRINO MIXING

In this section we derive the BBN constraints on the elements of the mixing matrix in the two schemes A and B. We follow the standard arguments [39–42,23] leading to the BBN constraints on the elements of the mixing matrix U if a sterile neutrino exists. According to the standard BBN scenario (see, for example, Ref. [28]) a lepton asymmetry can be neglected and the active neutrinos are in chemical equilibrium. Thus, the following considerations are valid for a temperature range $T_{\text{dec}} \lesssim T \lesssim 100$ MeV with the decoupling temperature $T_{\text{dec}} \sim 2$ MeV for electron neutrinos and $T_{\text{dec}} \sim 4$ MeV for muon and tau neutrinos. In this temperature region, the effective potentials of neutrinos due to coherent forward scattering in the primordial plasma are given by [43,41,42]

$$V_e \equiv V = -6.02 G_F p \frac{T^4}{M_W^2}, \quad V_{\mu,\tau} = \xi V \quad \text{and} \quad V_s = 0 \quad (3.1)$$

where p is the neutrino momentum, which henceforth will be replaced by its temperature average $\langle p \rangle \simeq 3.15 T$, and $\xi = \cos^2 \theta_W / (2 + \cos^2 \theta_W) \simeq 0.28$. The propagation of neutrinos⁴ is governed by the effective hamiltonian [19]

$$\begin{aligned} H_\nu &= \frac{1}{2p} U \text{diag}(m_1^2, m_2^2, m_3^2, m_4^2) U^{-1} + \text{diag}(V, \xi V, \xi V, 0) \\ &= U' \text{diag}(E_1, E_2, E_3, E_4) U'^{-1}, \end{aligned} \quad (3.2)$$

where E_1, E_2, E_3, E_4 are the effective energy eigenvalues of neutrinos in matter and U' is the corresponding effective mixing matrix. The amount of sterile neutrinos present at nucleosynthesis can be calculated using the differential equation [39]

$$\frac{dn_{\nu_s}}{dt} = \frac{1}{2} \sum_{\alpha=e,\mu,\tau} \langle P_{\nu_\alpha \rightarrow \nu_s} \rangle_{\text{coll}} \Gamma_{\nu_\alpha} (1 - n_{\nu_s}) \quad (3.3)$$

where n_{ν_s} is the number density of the sterile neutrino relative to the number density of an active neutrino in equilibrium and Γ_{ν_α} are the collision rates of the active neutrinos, including elastic and inelastic scattering [42], given by

$$\Gamma_{\nu_e} = 4.0 G_F^2 T^5 \quad \text{and} \quad \Gamma_{\nu_\mu, \nu_\tau} = B \Gamma_{\nu_e} \quad \text{with} \quad B = 0.722. \quad (3.4)$$

Let us notice some important characteristics of Eq.(3.3):

- i. The probabilities for $\nu_\alpha \rightarrow \nu_s$ transitions are averaged over the collision time $t_{\text{coll}} = 1/\Gamma_{\nu_e}$ and also n_{ν_s} has to be considered as such an averaged quantity.

⁴In the absence of a lepton asymmetry the neutrinos and antineutrinos evolve identically and hence only neutrinos are considered here.

- ii. This equation should approximately hold for non-resonant and adiabatic resonant neutrino transitions, as long as the active neutrinos are in chemical equilibrium and $t_{\text{osc}} \ll t_{\text{coll}} \ll t_{\text{exp}}$ is fulfilled. The characteristic expansion time of the universe t_{exp} is given by $t_{\text{exp}} = 1/H$ where H is the Hubble parameter, which is related to the temperature T by $H = -\dot{T}/T \simeq 0.69 (T/1 \text{ MeV})^2 \text{ s}^{-1}$.
- iii. The condition $t_{\text{osc}} \ll t_{\text{coll}}$ means that neutrino oscillations have to be fast relative to the collision time. The relation $\Gamma_{\nu_e}/H \simeq 1.2 (T/1 \text{ MeV})^3$ shows that for temperatures larger than 2 MeV the collision time is always much smaller than the expansion time [39].
- iv. Chemical equilibrium for the active neutrinos is maintained at temperatures larger than the neutrino decoupling temperature even in the presence of sterile neutrinos, provided the relevant mixing angles in the primordial plasma are not too large [42].

Using the relation $H = -\dot{T}/T$, the evolution equation (3.3) for n_{ν_s} can be rewritten as

$$\frac{dn_{\nu_s}}{dT} = -\frac{1}{2HT} \sum_{\alpha=e,\mu,\tau} \langle P_{\nu_\alpha \rightarrow \nu_s} \rangle_{\text{coll}} \Gamma_{\nu_\alpha} (1 - n_{\nu_s}). \quad (3.5)$$

Since by definition N_ν is the effective number of massless neutrino species at T_{dec} , in order to get a constraint on the mixing of sterile neutrinos we need to calculate the value of n_{ν_s} at T_{dec} produced by neutrino oscillations. With the initial condition $n_{\nu_s}(T_i) = 0$ ($T_i \sim 100$ MeV), the integration of Eq.(3.5) gives [44]

$$n_{\nu_s}(T_{\text{dec}}) = 1 - \exp \left(- \int_{T_{\text{dec}}}^{T_i} \frac{1}{2HT} \sum_{\alpha=e,\mu,\tau} \langle P_{\nu_\alpha \rightarrow \nu_s} \rangle_{\text{coll}} \Gamma_{\nu_\alpha} dT \right) \equiv 1 - \exp(-F). \quad (3.6)$$

Imposing the upper bound

$$n_{\nu_s}(T_{\text{dec}}) \leq \delta N \equiv N_\nu - 3, \quad (3.7)$$

one obtains the condition

$$F \leq |\ln(1 - \delta N)|. \quad (3.8)$$

Since c_e is small in scheme A and $1 - c_e$ is small in scheme B (see Eqs.(2.7) and (2.8)), they do not have any effect on neutrino oscillations during BBN. Hence in this Section we use the approximation $c_e = 0$ in scheme A and the approximation $1 - c_e = 0$ in scheme B [23]. In this case, the elements U_{ei} and U_{si} ($i = 1, \dots, 4$) of the mixing matrix can be chosen real and can be parameterized by

$$(U_{ei}) = (0, 0, c_\theta, s_\theta), \quad (U_{si}) = (s_\varphi s_\chi, -s_\varphi c_\chi, -c_\varphi s_\theta, c_\varphi c_\theta) \quad \text{in scheme A}, \quad (3.9)$$

$$(U_{ei}) = (c_\theta, s_\theta, 0, 0), \quad (U_{si}) = (s_\varphi s_\theta, -s_\varphi c_\theta, -c_\varphi s_\chi, c_\varphi c_\chi) \quad \text{in scheme B}, \quad (3.10)$$

with the abbreviations $c_\rho \equiv \cos \rho$ and $s_\rho \equiv \sin \rho$ for $\rho = \theta, \chi, \varphi$ and $0 \leq \varphi \leq \pi/2$. In both schemes A and B we have $c_s = \sin^2 \varphi$.

Then, it can be shown that [23]

$$\sum_{\alpha=e,\mu,\tau} \langle P_{\nu_\alpha \rightarrow \nu_s} \rangle_{\text{coll}} \Gamma_{\nu_\alpha} = \frac{B \Gamma_{\nu_e}}{2} \left\{ \frac{D^2 \sin^2 2\chi}{1 - 2D\xi x_{\text{atm}} \cos 2\chi + D^2(\xi x_{\text{atm}})^2} + \frac{4c_s(1 - c_s)}{1 - 2\xi x_{\text{SBL}}(1 - 2c_s) + (\xi x_{\text{SBL}})^2} \right\} \quad (3.11)$$

where

$$x_\sigma \equiv \frac{2pV}{\Delta m_\sigma^2} = -2.18 \times 10^{-7} \left(\frac{\Delta m_\sigma^2}{1 \text{ eV}^2} \right)^{-1} \left(\frac{T}{1 \text{ MeV}} \right)^6 \quad (\sigma = \text{atm, SBL}) \quad (3.12)$$

and p is replaced by its temperature average. With the definitions

$$D \equiv c_s \quad \text{in scheme A} \quad \text{and} \quad D \equiv 1 - c_s \quad \text{in scheme B}, \quad (3.13)$$

Eq. (3.11) holds in both schemes. The two terms in Eq. (3.11) correspond to oscillations due to Δm_{atm}^2 and Δm_{SBL}^2 , respectively. Oscillations due to Δm_{sun}^2 are neglected in Eq.(3.11) because their contribution to F (see Eq.(3.6)) is at least two orders of magnitude smaller for $T > T_{\text{dec}}$.

Using the expression (3.11) one can find an analytic form of the integral (3.6) and the condition (3.8) gives the bound

$$920 \left(\frac{\Delta m_{\text{SBL}}^2}{1 \text{ eV}^2} \right)^{1/2} c_s \sqrt{1 - c_s} + 33 \left(\frac{\Delta m_{\text{atm}}^2}{10^{-2} \text{ eV}^2} \right)^{1/2} \frac{\sin^2 2\chi}{\sqrt{1 + \cos 2\chi}} D^{3/2} \leq |\ln(1 - \delta N)|. \quad (3.14)$$

With the definitions (3.13) this bound holds for both schemes, provided the conditions laid down in i.-iv. are fulfilled.

Let us now discuss the implications of the bound (3.14). In order to understand if this bound is compatible with a large D , we first consider the possibility that D is close to one. In this case we have $(U_{\mu 1}, U_{\mu 2}) \sim (\cos \chi, \sin \chi)$ in scheme A and $(U_{\mu 3}, U_{\mu 4}) \sim (\cos \chi, \sin \chi)$ in scheme B. This means that, in order to accommodate the atmospheric neutrino anomaly, $\sin^2 2\chi$ cannot be small. However, this is in contradiction with the inequality (3.14) because of the second term in the left-hand side. Therefore, we conclude that the bound (3.14) implies that D is small, i.e. c_s is small in scheme A and $1 - c_s$ is small in scheme B.

Let us now check the validity of this reasoning considering the oscillations due to Δm_{atm}^2 which generate the second term in Eq.(3.14) and taking into account that the method considered here only holds for non-resonant neutrino oscillations or adiabatic transitions through a resonance. Looking at Eq.(3.11) we see that there is a resonant behaviour of the oscillations due to Δm_{atm}^2 at the temperature where the relation $D\xi x_{\text{atm}} = \cos 2\chi$ is satisfied. Since x_{atm} is negative, this is only possible if $\cos 2\chi$ is negative. However, since we do not know the sign of $\cos 2\chi$, we have to check if the resonance is crossed adiabatically in the case of a negative sign. A measure of the adiabaticity of the resonance is given by the parameter

$$q_{\text{atm}} = \left| \frac{1}{\Delta E_{\text{atm}}} \frac{d\chi'}{dt} \right|_{\text{max}} = 1.23 \times 10^{-4} \left(\frac{\Delta m_{\text{atm}}^2}{10^{-2} \text{ eV}^2} \right)^{-1/2} \frac{\sin 2\chi}{\sqrt{D} (1 + \cos 2\chi)^{3/2}} \quad (3.15)$$

where ΔE_{atm} and χ' are the oscillation frequency and the effective mixing angle in matter. If $q_{\text{atm}} \ll 1$ the adiabatic crossing of the resonance is guaranteed. Clearly, for $D \sim 1$ and $\sin^2 2\chi \sim 1$ this condition is fulfilled. Furthermore, oscillations due to Δm_{atm}^2 occur around the temperature $T_{\text{atm}} \sim 7D^{-1/6}$ MeV, where $D|\xi x_{\text{atm}}| \sim 1$. One can show that for $D \sim 1$ the relation $t_{\text{osc}} \ll t_{\text{coll}}$ holds for resonant and non-resonant oscillations due to Δm_{atm}^2 and thus the conditions for the validity of Eq.(3.3) and all relations derived from it are fulfilled as well. Consequently, the exclusion of the case $D \sim 1$ with the help of the second term in Eq.(3.14) is correct. It is interesting to note that no conclusions can be drawn from the second term in Eq.(3.14) if $D \lesssim 0.1$ because then $T_{\text{atm}} \gtrsim 10$ MeV and in this temperature region one has $t_{\text{osc}} \gg t_{\text{coll}}$ and therefore no oscillations due to Δm_{atm}^2 are possible because of strong quantum damping.

Let us now examine the implications of the first term in Eq.(3.14). The presence of this term implies that either c_s or $\sqrt{1 - c_s}$ has to be very small. As we have just shown considering the second term in Eq.(3.14), in scheme A c_s is small. This implies that $1 - 2c_s > 0$ and only non-resonant oscillations are possible (see the last term in Eq.(3.11)). Hence, Eq.(3.14) is valid in scheme A and the first term gives the bound

$$c_s \leq 1.1 \times 10^{-3} \left(\frac{\Delta m_{\text{SBL}}^2}{1 \text{ eV}^2} \right)^{-1/2} |\ln(1 - \delta N)| \equiv \mathcal{B}^{(A)}. \quad (3.16)$$

On the other hand, considering the second term in Eq.(3.14), we have shown that in scheme B the quantity $1 - c_s$ is small. Therefore, in scheme B we have $1 - 2c_s < 0$ and a resonance occurs at the temperature $T_{\text{res}} = 16(\Delta m_{\text{SBL}}^2/1 \text{ eV}^2)^{1/6}|1 - 2c_s|^{1/6}$ MeV, where $\xi x_{\text{SBL}} = 1 - 2c_s$. One can show that this resonance is not passed adiabatically, hence the conditions for the validity of Eq.(3.3) are not fulfilled and the first term of Eq.(3.14) does not apply. In this case the amount of sterile neutrinos produced at the resonance through non-adiabatic transitions can be calculated with the formula [45,46]

$$n_{\nu_s} = \frac{1}{2} - \left(\frac{1}{2} - P_{LZ} \right) \cos 2\varphi_b \cos 2\varphi_a \simeq 1 - P_{LZ}, \quad (3.17)$$

where φ_b (φ_a) is the effective mixing angle before (after) the resonance. The last approximation in Eq.(3.17) follows from the fact that $\cos 2\varphi_b \simeq 1$ because of the high effective neutrino potential before the resonance and $\cos 2\varphi_a \simeq \cos 2\varphi = 1 - 2c_s \simeq -1$ for small $1 - c_s$. The quantity $P_{LZ} = \exp(-Q)$ is the Landau-Zener probability [47] and Q is given by [45,42,46]

$$Q \equiv \frac{\pi^2}{2} \frac{\delta t}{t_{\text{osc}}} = \frac{2\pi}{\hbar} \frac{c_s(1 - c_s)}{|1 - 2c_s|} \left| V \left(\frac{dx_{\text{SBL}}}{dt} \right)^{-1} \right|_{T_{\text{res}}} \\ \simeq 9.2 \times 10^4 \frac{c_s(1 - c_s)}{|1 - 2c_s|^{3/2}} \left(\frac{\Delta m_{\text{SBL}}^2}{1 \text{ eV}^2} \right)^{1/2}, \quad (3.18)$$

where δt is the half-width of the resonance defined in Ref. [41]. Demanding again that $n_{\nu_s} \leq \delta N$ one obtains the condition $Q \leq |\ln(1 - \delta N)|$ which gives the bound

$$1 - c_s \leq 1.1 \times 10^{-5} \left(\frac{\Delta m_{\text{SBL}}^2}{1 \text{ eV}^2} \right)^{-1/2} |\ln(1 - \delta N)| \equiv \mathcal{B}^{(B)} \quad (3.19)$$

in scheme B. The linear approximation of the potential used to derive the Landau–Zener formula is valid if the potential changes slowly in the resonance region. At the resonance one obtains $|V/(dV/dt)|/\delta t \sim |1 - 2c_s|/2\sqrt{c_s(1 - c_s)}$ which is large for small $1 - c_s$. Hence the linear approximation should apply.

In the following table we show the values of the bounds $\mathcal{B}^{(A)}$ and $\mathcal{B}^{(B)}$ obtained from Eqs.(3.16) and (3.19) and the LSND lower bound $\Delta m_{\text{SBL}}^2 \gtrsim 0.27 \text{ eV}^2$ (see Eq.(2.6)) for different values of δN :

	δN	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	
scheme A:	$\mathcal{B}^{(A)}/10^{-3}$	4.8	3.4	2.5	1.9	1.4	1.1	0.7	0.5	(3.20)
scheme B:	$\mathcal{B}^{(B)}/10^{-5}$	4.9	3.4	2.6	1.9	1.5	1.1	0.8	0.5	

The bounds (3.16) for the non-resonant oscillations in scheme A and (3.19) for the resonant case in scheme B are in rough agreement with the corresponding numerical integrations of the evolution equations of an ensemble of oscillating neutrinos which take into account 2-neutrino oscillations [42,46].

Let us now summarize our findings. The constraints on the parameter c_s in scheme A (Eq.(3.16)) and $1 - c_s$ in scheme B (Eq.(3.19)) has been derived in both schemes from the oscillations due to Δm_{SBL}^2 at temperatures of the order $T \sim 16 \text{ MeV}$ where $\xi|x_{\text{SBL}}| \sim 1$. The second term in Eq.(3.14), which is generated by the oscillations due to Δm_{atm}^2 , only serves to exclude large D . The transitions of active into sterile neutrinos due to Δm_{SBL}^2 are non-resonant in scheme A, whereas they are resonant in scheme B, leading to a stronger constraint on $1 - c_s$ than the constraint on c_s in scheme A (see table (3.20)). We have obtained stronger bounds than Ref. [23] because we have taken into account the complete collision rates (3.4) presented in Ref. [42], which are nearly an order of magnitude larger than those used in Ref. [23]. Furthermore, our method shows that the dependence of the bound on c_s in scheme A and $1 - c_s$ in scheme B on the allowed number of neutrino species N_ν is logarithmic [44].

We want to emphasize that our calculation of the amount of sterile neutrinos brought into equilibrium by oscillations before the onset of BBN is based upon equation (3.3) in scheme A and upon the Landau–Zener approximation in scheme B. Therefore, the numbers given in table (3.20) should be viewed as order of magnitude estimates of the upper bounds on the parameter c_s in scheme A and $1 - c_s$ in scheme B.

Concluding this section, we would like to make some comments on the non-standard BBN scenario with a non-zero lepton asymmetry presented in Ref. [48]. There it has been shown that for a certain range of the mixing parameters and for resonant transitions due to Δm_{SBL}^2 a lepton asymmetry as small as 10^{-10} can be amplified up to 10^{-2} and in this way transitions at a lower temperature (like the transitions due to Δm_{atm}^2 in the schemes under consideration) can be prevented. Such a scenario would not change our bound for $1 - c_s$ in scheme B, but could have some effect on our considerations for scheme A. If c_s is large in scheme A, a resonance due to Δm_{SBL}^2 occurs and, if a large lepton asymmetry is generated, the oscillations due to Δm_{atm}^2 are suppressed and the second term on the left-hand side of Eq.(3.14) is not valid. Hence a large parameter c_s cannot be excluded. Therefore, contrary to our discussion in this section, in this case we would have two possibilities for scheme A: either c_s is small and has to obey the bound (3.16) or c_s is close to one and $1 - c_s$ has to

obey the same bound as given in Eq.(3.19) for scheme B. However, judging from the results of Ref. [48] it has yet to be shown that with c_s close to one a realistic scenario meeting all experimental constraints can actually be achieved in scheme A and we leave this problem to future investigation.

IV. TERRESTRIAL NEUTRINO OSCILLATION EXPERIMENTS AND STERILE NEUTRINO MIXING

As we have shown in the previous Section, BBN suggests that the parameter c_s in scheme A ($1 - c_s$ in scheme B) is small. In this Section we present some possibilities to obtain information on the parameter c_s from future results of SBL and LBL neutrino oscillation experiments. We consider explicitly scheme A, but the same results are valid in scheme B after the replacement of c_s with $1 - c_s$.

Let us start with the consideration of $\nu_\mu \rightarrow \nu_\tau$ oscillations, that are presently searched for in the CHORUS [49] and NOMAD [50] experiments and will be searched for in the COSMOS [51] experiment. From Eq.(2.3), for the amplitude of $\nu_\mu \rightarrow \nu_\tau$ oscillations we have the upper bound

$$A_{\mu;\tau} \leq 4(1 - c_\mu)(1 - c_\tau). \quad (4.1)$$

The unitarity of the mixing matrix implies that

$$\sum_{\alpha} c_{\alpha} = 2 \quad (4.2)$$

and Eq.(4.1) can be rewritten as

$$A_{\mu;\tau} \leq 4(1 - c_\mu)[c_e + c_s - (1 - c_\mu)]. \quad (4.3)$$

Since the quantity $1 - c_\mu$ satisfies the inequality (2.7), if

$$c_e + c_s \geq 2a_\mu^0 \quad (4.4)$$

we have

$$A_{\mu;\tau} \leq 4a_\mu^0(c_e + c_s - a_\mu^0) \leq 4a_\mu^0(a_e^0 + c_s). \quad (4.5)$$

On the other hand, if the inequality

$$c_e + c_s \leq 2a_\mu^0 \quad (4.6)$$

is satisfied, for the amplitude $A_{\mu;\tau}$ we have

$$A_{\mu;\tau} \leq (c_e + c_s)^2 \leq 4(a_\mu^0)^2. \quad (4.7)$$

As it is seen from Eqs.(4.5) and (4.7), if it will be found that the amplitude $A_{\mu;\tau}$ satisfies the inequality

$$A_{\mu;\tau} > 4(a_\mu^0)^2, \quad (4.8)$$

it will mean that the parameter c_s must satisfy the inequality

$$c_s \geq 2a_\mu^0 - a_e^0 \quad (4.9)$$

and is in general not small. In Fig.1 we have plotted the values of $4(a_\mu^0)^2$ (solid curve) and $B_{\mu;\mu}^0$ (dashed curve) obtained from the 90% CL exclusion curves of the CDHS [36] and CCFR [37] experiments in the range (2.5) of Δm_{SBL}^2 , that covers the LSND-allowed region. The dashed curve representing $B_{\mu;\mu}^0$ constitutes an upper bound for $A_{\mu;\tau}$ due to the conservation of probability. Therefore, if the inequality (4.8) is satisfied, $A_{\mu;\tau}$ must lie between the solid and dashed curves. In Fig.1 we have also plotted the most recent exclusion curve presented by the CHORUS collaboration [52] (dash-dotted curve), the expected final sensitivity of the CHORUS [49] and NOMAD [50] experiments (dash-dot-dotted curve) and the expected sensitivity of the COSMOS [51] experiment (dotted curve). One can see that a substantial part of the region in which the inequality (4.8) is satisfied is already ruled out by the present CHORUS exclusion curve, a large part will be excluded when the final sensitivities of the CHORUS and NOMAD experiments will be reached and almost all the region will be excluded if the COSMOS experiment will not find $\nu_\mu \rightarrow \nu_\tau$ oscillations.

In Fig.2 we have plotted the values of $2a_\mu^0 - a_e^0$ obtained from the 90% CL exclusion curves of the Bugey [35], CDHS [36] and CCFR [37] experiments. One can see that for the values of Δm_{SBL}^2 in which $a_e^0 < 2a_\mu^0$, if the inequality (4.8) is satisfied c_s must be large and incompatible with the BBN upper bound. On the other hand, for the values of Δm_{SBL}^2 in which $a_e^0 > 2a_\mu^0$, c_s does not need to be large (the inequality (4.4) is satisfied because c_e can be larger than $2a_\mu^0$) and there is no contradiction with the BBN upper bound on c_s even if the inequality (4.8) is satisfied. If $A_{\mu;\tau}$ will be measured and found to satisfy the inequality (4.8), also Δm_{SBL}^2 will be determined with some accuracy. In this case, depending on the allowed range of Δm_{SBL}^2 , it will be possible to decide if a small c_s compatible with the BBN upper bound is excluded or not. Note, however, that for the LSND range (2.6) of Δm_{SBL}^2 the parameter c_s must be large if the inequality (4.8) is satisfied.

Furthermore, if some future experiment will measure a value of $A_{\mu;\tau}$ such that Eq.(4.8) is satisfied, then the inequality (4.5) will imply in addition the lower bound

$$c_s \geq \frac{A_{\mu;\tau}}{4a_\mu^0} - a_e^0, \quad (4.10)$$

which is more stringent than the lower bound (4.9) if $A_{\mu;\tau} > 8(a_\mu^0)^2$.

Let us now consider the possibility that a future experiment will measure a small value for the amplitude $A_{\mu;\tau}$, i.e. such that the inequality (4.7) is satisfied. This measurement will not give any information on the value of c_s . In this case, the BBN bound derived in Section III implies that $c_s \simeq 0$ and for the amplitude $A_{\mu;\tau}$ we have the upper bound

$$A_{\mu;\tau} \leq (a_e^0)^2. \quad (4.11)$$

The numerical values of this upper bound in the range (2.5) of Δm_{SBL}^2 obtained from the 90% CL exclusion curve of the Bugey [35] experiment is shown in Fig.3 (solid curve), together with the most recent exclusion curve presented by the CHORUS collaboration [52]

(dash-dotted curve), the expected final sensitivity of the CHORUS [49] and NOMAD [50] experiments (dash-dot-dotted curve) and the expected sensitivity of the COSMOS [51] experiment (dotted curve).

Thus, we have seen that the investigation of $\nu_\mu \rightarrow \nu_\tau$ oscillations in the region of Δm_{SBL}^2 that includes the LSND-allowed region could allow to obtain information on the value of the parameter c_s that is important for BBN.

Let us consider now the possibility to obtain information on the parameter c_s from the data of inclusive $\nu_\mu \rightarrow \nu_\mu$ and $\bar{\nu}_e \rightarrow \bar{\nu}_e$ experiments. From Eqs.(2.4) and (2.7) it follows that

$$c_e = \frac{1}{2} \left(1 - \sqrt{1 - B_{e;e}} \right), \quad (4.12)$$

$$1 - c_\mu = \frac{1}{2} \left(1 - \sqrt{1 - B_{\mu;\mu}} \right). \quad (4.13)$$

Furthermore, from Eq.(4.2) we have

$$c_s \geq (1 - c_\mu) - c_e. \quad (4.14)$$

From Eqs.(4.12)–(4.14) we obtain the inequality

$$c_s \geq \frac{1}{2} \left(\sqrt{1 - B_{e;e}} - \sqrt{1 - B_{\mu;\mu}} \right). \quad (4.15)$$

The amplitude $B_{e;e}$ is small in the whole range (2.5) of Δm_{SBL}^2 . If the parameter c_s is small as suggested by BBN, also the amplitude $B_{\mu;\mu}$ must be small. The existing data do not exclude, however, large values of $B_{\mu;\mu}$ for $\Delta m_{\text{SBL}}^2 \lesssim 0.3 \text{ eV}^2$. Hence, our analysis shows that the investigation of inclusive $\nu_\mu \rightarrow \nu_\mu$ transitions for $\Delta m_{\text{SBL}}^2 \lesssim 0.3 \text{ eV}^2$ would be interesting for the check of the constraint that follows from BBN.

Let us now consider the amplitude $A_{e;s}$ of $\nu_e \rightarrow \nu_s$ oscillations. From the upper bound

$$A_{e;s} \leq 4 c_e c_s \leq 4 a_e^0 c_s, \quad (4.16)$$

which follows from Eqs.(1.6), (2.3) and (2.7), it is clear that the BBN bound on c_s implies that $A_{e;s}$ is extremely small. In this case the amplitudes measured in SBL ν_e disappearance experiments and SBL $\nu_e \rightarrow \nu_\mu$ and $\nu_e \rightarrow \nu_\tau$ appearance experiments are related by

$$B_{e;e} \simeq A_{\mu;e} + A_{e;\tau}. \quad (4.17)$$

The experimental check of this relation allows to test the BBN bound on c_s . Indeed, if SBL ν_e disappearance experiments will find neutrino oscillations with a lower limit $B_{e;e}^{(\text{min})}$ for the amplitude $B_{e;e}$ such that $B_{e;e}^{(\text{min})} > A_{\mu;e}^{(\text{max})} + A_{e;\tau}^{(\text{max})}$, where $A_{\mu;e}^{(\text{max})}$ and $A_{e;\tau}^{(\text{max})}$ are the experimental upper limit for $A_{\mu;e}$ and $A_{e;\tau}$, respectively, it will mean that $A_{e;s} > 0$. In this case, taking into account that $B_{e;e} = A_{\mu;e} + A_{e;\tau} + A_{e;s}$ and that for small $B_{e;e}$ we have $c_e \simeq B_{e;e}/4$, the inequality $A_{e;s} \leq 4 c_e c_s$ gives the lower bound

$$c_s \geq \frac{A_{e;s}}{4 c_e} \simeq 1 - \frac{A_{\mu;e} + A_{e;\tau}}{B_{e;e}} \geq 1 - \frac{A_{\mu;e}^{(\text{max})} + A_{e;\tau}^{(\text{max})}}{B_{e;e}^{(\text{min})}}. \quad (4.18)$$

If, for example, it will be found that⁵ $B_{e;e}^{(\min)} \simeq 10^{-2}$, $A_{\mu;e}^{(\max)} \simeq 5 \times 10^{-3}$ and $A_{e;\tau}^{(\max)} \ll A_{\mu;e}^{(\max)}$, Eq.(4.18) will imply the lower bound $c_s \gtrsim 0.5$, which is incompatible with the BBN upper bound.

CP violation in long-baseline neutrino oscillation experiments can also be used to check the BBN constraint on c_s , though in practice this possibility is more remote. It has been shown in Ref. [25] that the absolute value of the CP-violating parameter $I_{\mu\tau} = 4 \text{Im}[U_{\mu 1} U_{\tau 1}^* U_{\mu 2}^* U_{\tau 2}]$ (in scheme A, whereas $I_{\mu\tau} = 4 \text{Im}[U_{\mu 3} U_{\tau 3}^* U_{\mu 4}^* U_{\tau 4}]$ in scheme B) could be as large as $2/3\sqrt{3}$, which is the maximal value allowed by the unitarity of the mixing matrix. With the method discussed in Ref. [25] one can show that

$$|I_{\mu\tau}| \leq (c_e + c_s) \sqrt{1 - c_e - c_s} \quad (4.19)$$

for small $c_e + c_s$. From the upper bound $c_e \leq a_e^0$ (see Eq.(2.7)) and the BBN upper bound $c_s \leq \mathcal{B}^{(A)}$ (see Eq.(3.16)) we have

$$|I_{\mu\tau}| \leq (a_e^0 + \mathcal{B}^{(A)}) \sqrt{1 - a_e^0 - \mathcal{B}^{(A)}}. \quad (4.20)$$

Consequently, taking into account that a_e^0 is small, the BBN upper bound on c_s implies that CP violation in the $\nu_\mu \rightarrow \nu_\tau$ channel is suppressed. On the other hand, if CP violation will be observed in LBL $\nu_\mu \rightarrow \nu_\tau$ experiments, using Eq.(4.19) it will be possible to set a lower bound for c_s . Analogous results are valid in scheme B with the replacements $c_e \rightarrow 1 - c_e$, $c_s \rightarrow 1 - c_s$ and $\mathcal{B}^{(A)} \rightarrow \mathcal{B}^{(B)}$.

V. A PARAMETERIZATION OF THE 4-NEUTRINO MIXING MATRIX

In this Section we propose a parameterization of the 4×4 mixing matrix U which is suitable for the two schemes A and B that allow to accommodate all existing neutrino oscillation data. In these schemes the neutrinos ν_1, ν_2 and the neutrinos ν_3, ν_4 give separate contributions to all observables. Thus, it is natural to consider separately the elements $U_{\alpha i}$ with $i = 1, 2$ and the elements $U_{\alpha k}$ with $k = 3, 4$. In the following we will stick to scheme A for the actual presentation. The formulas in scheme B can be obtained with the exchanges $1 \leftrightarrow 3$ and $2 \leftrightarrow 4$ of the columns of U .

We take into account that all observable transition probabilities are invariant under the phase transformation

$$U_{\alpha j} \rightarrow e^{ix_\alpha} U_{\alpha j} e^{iy_j} \quad (5.1)$$

⁵These values are compatible with the present upper bound for $B_{e;e}$, which is given by the results of the Bugey [35] experiment, and with the present allowed range of $A_{\mu;e}$, which is given by the results of the LSND [15] and Bugey experiments ($B_{e;e} \lesssim 4 \times 10^{-2}$ and $2 \times 10^{-3} \lesssim A_{\mu;e} \lesssim 4 \times 10^{-2}$ for Δm_{SBL}^2 in the LSND range (2.6)). Notice that the allowed range of $A_{\mu;e}$ will be checked in the near future by KARMEN [53] and other experiments [54]. Furthermore, information on $A_{e;\tau}$ could be obtained in the future in experiments using a ν_e beam from a muon collider (see Refs. [55,56]).

where x_α and y_j are arbitrary parameters. Therefore, U_{ek} with $k = 3, 4$ and $U_{\mu i}$ with $i = 1, 2$ can always be considered as real vectors. Let us write them as

$$U_{ek} = r_e v_{k-2} \quad (k = 3, 4), \quad (5.2)$$

$$U_{\mu i} = p_\mu w_i \quad (i = 1, 2), \quad (5.3)$$

with

$$r_e = \sqrt{\sum_{k=3,4} |U_{ek}|^2} \quad \text{and} \quad p_\mu = \sqrt{\sum_{i=1,2} |U_{\mu i}|^2}. \quad (5.4)$$

The unit vectors v and w can be written in the form

$$v = (\cos \theta, \sin \theta) \quad \text{and} \quad w = (\cos \gamma, \sin \gamma). \quad (5.5)$$

Let us introduce also the orthogonal unit vectors

$$v^\perp = (-\sin \theta, \cos \theta) \quad \text{and} \quad w^\perp = (-\sin \gamma, \cos \gamma). \quad (5.6)$$

Then the vectors $U_{\alpha i}$ with $\alpha \neq e$ and $i = 3, 4$ can be expanded over the orthonormal basis $\{v, v^\perp\}$ and the vectors $U_{\alpha i}$ with $\alpha \neq \mu$ and $i = 1, 2$ can be expanded over the orthonormal basis $\{w, w^\perp\}$. As a result, we have the parameterization

$$U = \begin{pmatrix} p_e w + q_e w^\perp & r_e v \\ p_\mu w & r_\mu v + s_\mu v^\perp \\ p_\tau w + q_\tau w^\perp & r_\tau v + s_\tau v^\perp \\ p_s w + q_s w^\perp & r_s v + s_s v^\perp \end{pmatrix} \quad (5.7)$$

for the mixing matrix. Using the invariance under the transformation (5.1), we can choose the parameters q_τ and s_s as real.

From Eqs.(1.6) and (5.4) it is obvious that the parameters r_e and p_μ are connected, respectively, with the parameters c_e and c_μ by the relations

$$r_e = \sqrt{1 - c_e}, \quad p_\mu = \sqrt{c_\mu}. \quad (5.8)$$

Furthermore, from the unitarity of U it follows that the parameters r_μ and p_e are related by

$$r_\mu = -p_e^* \sqrt{\frac{c_\mu}{1 - c_e}}. \quad (5.9)$$

Similarly, we can think of q_τ and s_s being fixed by the unit length of the lines of U and five of the remaining complex parameters by the orthogonality of different lines. Counting the number of remaining real parameters in U we obtain 10 versus 9 physical real parameters in a 4×4 unitary mixing matrix. A careful inspection of the residual phase freedom reveals that one of the complex parameters $p_e, q_e, r_\mu, s_\mu, p_\tau, r_\tau, s_\tau, p_s, q_s$ or r_s can be chosen real in addition.

The significance of the parameters in the matrix (5.7) shows up by considering the amplitudes of neutrino oscillations in disappearance and appearance SBL experiments, which are directly connected with the parameters p_α and r_α . In fact, we have

$$B_{e;e} = 4r_e^2(1 - r_e^2), \quad B_{\mu;\mu} = 4p_\mu^2(1 - p_\mu^2) \quad (5.10)$$

and

$$A_{\mu;e} = 4|p_e|^2 p_\mu^2, \quad A_{e;\tau} = 4|r_\tau|^2 r_e^2, \quad A_{\mu;\tau} = 4|p_\tau|^2 p_\mu^2. \quad (5.11)$$

The SBL oscillation amplitudes do not contain the angles θ and γ . This is connected with the fact that SBL amplitudes are determined by products of vectors in the 1, 2 space or in the 3, 4 space (see Eqs.(2.3) and (2.4)). However, information on the angle γ can be obtained from the results of atmospheric and LBL neutrino experiments, whereas the results of solar neutrino experiments give information on the angle θ .

In the four-neutrino scheme A the parameters p_e, q_e are small because $c_e = |p_e|^2 + |q_e|^2$ is small (see Eq.(2.7)). Let us now investigate if it is possible to obtain bounds on the parameters $|p_s|^2$ and $|q_s|^2$ from measurable quantities. We will use the unitarity of the mixing matrix and we will work in the approximation $c_e = 0$. In this case, the parameterization (5.7) of the mixing matrix reduces to

$$U \simeq \begin{pmatrix} 0 & v \\ p_\mu w & s_\mu v^\perp \\ p_\tau w + q_\tau w^\perp & s_\tau v^\perp \\ p_s w + q_s w^\perp & s_s v^\perp \end{pmatrix} \quad (5.12)$$

and the amplitude of $\nu_\mu \rightarrow \nu_\tau$ oscillations is given by (see Eq.(2.3))

$$A_{\mu;\tau} = 4|s_\mu|^2 |s_\tau|^2. \quad (5.13)$$

Furthermore, taking into account that

$$|p_\tau|^2 + |q_\tau|^2 + |s_\tau|^2 = 1, \quad (5.14)$$

$$|q_\tau|^2 + |q_s|^2 = 1, \quad (5.15)$$

we have

$$|q_s|^2 = |s_\tau|^2 + |p_\tau|^2 \geq |s_\tau|^2. \quad (5.16)$$

From Eqs.(5.13) and (5.16) and taking into account that $|s_\mu|^2 = 1 - c_\mu \leq a_\mu^0$ (see Eq.(2.7)), we obtain

$$|q_s|^2 \geq \frac{A_{\mu;\tau}}{4a_\mu^0}. \quad (5.17)$$

This lower bound for $|q_s|^2 = c_s - |p_s|^2$, obtained in the approximation $a_e^0 = 0$, is consistent with the lower bound (4.10) on c_s . From the comparison of these two lower bounds it is clear that if c_s is large, its value approximately coincides with $|q_s|^2$, whereas $|p_s|^2$ is small if a_μ^0 is small. Indeed, it is possible to obtain an upper bound for the parameter $|p_s|^2$ using the unitarity relation

$$p_\mu p_s^* + s_\mu s_s^* = 0. \quad (5.18)$$

Taking into account that

$$|s_\mu|^2 = 1 - p_\mu^2, \quad (5.19)$$

$$|s_s|^2 = 1 - |p_s|^2 - |q_s|^2, \quad (5.20)$$

we find from Eq.(5.18)

$$\frac{|p_s|^2}{1 - |q_s|^2} = 1 - p_\mu^2. \quad (5.21)$$

Since $1 - p_\mu^2 = 1 - c_\mu \leq a_\mu^0$ (see Eq.(2.7)), we obtain the upper bound

$$|p_s|^2 \leq a_\mu^0. \quad (5.22)$$

Therefore, if the experimental upper bound for the amplitude of SBL $\nu_\mu \rightarrow \nu_\mu$ transitions is small, $|p_s|^2$ is small as well.

Note that the observation of SBL inclusive $\nu_\mu \rightarrow \nu_\mu$ transitions together with the observation of SBL $\nu_\mu \rightarrow \nu_\tau$ and $\nu_\mu \rightarrow \nu_e$ (LSND [15]) transitions would allow to get information on the transitions of muon neutrinos into sterile states. In fact, because of the unitarity of the mixing matrix, for the amplitude $A_{\mu;s}$ of $\nu_\mu \rightarrow \nu_s$ transitions we have

$$A_{\mu;s} = B_{\mu;\mu} - A_{\mu;e} - A_{\mu;\tau}. \quad (5.23)$$

Hence, we think that it is important to continue the search for neutrino oscillations in the inclusive $\nu_\mu \rightarrow \nu_\mu$ channel, especially in the region of small Δm_{SBL}^2 , below 0.3 eV^2 , which has not been explored so far. Let us consider the possibility that the right side of Eq.(5.23) will be measured to be different from zero, i.e., that $\nu_\mu \rightarrow \nu_s$ transitions occur in SBL experiments. In the scheme under consideration the amplitude of these transitions is given by

$$A_{\mu;s} = 4 p_\mu^2 |p_s|^2. \quad (5.24)$$

Taking into account that $p_\mu^2 = c_\mu$, Eqs.(4.13), (5.23) and (5.24) imply that

$$|p_s|^2 = \frac{B_{\mu;\mu} - A_{\mu;e} - A_{\mu;\tau}}{2(1 + \sqrt{1 - B_{\mu;\mu}})}. \quad (5.25)$$

Finally, if it will be found that not only $\nu_e \rightarrow \nu_e$ SBL transitions but also $\nu_\mu \rightarrow \nu_\mu$ SBL transitions are strongly suppressed, it will mean that the only oscillation channel involving sterile neutrinos which may be not suppressed is the channel $\nu_\tau \rightarrow \nu_s$. Therefore, in this case it will be possible to obtain information on transitions of active neutrinos into sterile states only if ν_τ beams (see Ref. [57]) will be available. In this case $|p_s|^2 \simeq 0$ and

$$B_{\tau;\tau} = A_{\tau;s} = 4 |q_s|^2 (1 - |q_s|^2). \quad (5.26)$$

Let us now consider the possibility that not only p_e, q_e but also p_s, q_s are small, as follows from the smallness of $c_s = |p_s|^2 + |q_s|^2$ implied by BBN if $N_\nu \lesssim 3.9$, as shown in Section III. In this case it is possible to expand all the quantities $p_\alpha, q_\alpha, r_\alpha$ and s_α in powers of the small

parameters p_e, q_e, p_s, q_s , up to order $c_e, c_s, \sqrt{c_e c_s}$. This means that in this approximation it is possible⁶ to express all elements of U in terms of the parameters $p_e, q_e, p_s, q_s, \theta$ and γ . Note that one of the phases of the small complex parameters is unphysical and can be transformed away reaching thus the number of 9 physically independent real parameters in U . Performing this program we obtain

$$\begin{aligned} |p_\mu|^2 &\simeq 1 - |p_e|^2 - |p_s|^2, & r_\mu &\simeq -p_e^*, & s_\mu &\simeq -p_s^*, \\ p_\tau &\simeq -p_e q_e^* - p_s q_s^*, & |q_\tau|^2 &\simeq 1 - |q_e|^2 - |q_s|^2, & r_\tau &\simeq -q_e^*, & s_\tau &\simeq -q_s^*, \\ r_s &\simeq -p_e^* p_s - q_e^* q_s, & |s_s|^2 &\simeq 1 - c_s. \end{aligned} \quad (5.27)$$

In this approximation, Eqs.(5.10) and (5.11) become

$$B_{e;e} \simeq 4(|p_e|^2 + |q_e|^2), \quad B_{\mu;\mu} \simeq 4(|p_e|^2 + |p_s|^2) \quad (5.28)$$

and

$$A_{\mu;e} \simeq 4|p_e|^2, \quad A_{e;\tau} \simeq 4|q_e|^2, \quad A_{\mu;\tau} \simeq 4|p_e q_e^* + p_s q_s^*|^2. \quad (5.29)$$

Therefore we have

$$B_{e;e} \simeq A_{\mu;e} + A_{e;\tau}. \quad (5.30)$$

The absolute value of p_s is given by

$$|p_s|^2 \simeq \frac{1}{4}(B_{\mu;\mu} - A_{\mu;e}). \quad (5.31)$$

In the absence of ν_τ disappearance experiments (see Eq.(5.26)), the determination of the parameter $|q_s|$ needs further information from LBL experiments. This is not an artifact of the expansion in Eq.(5.27). The reason is that $B_{\mu;\mu}$ and $A_{\mu;\tau}$ are small if $|p_s|$ is small and this is true even if $|q_s|$ is large, i.e. c_s is large. This explains the limitations in our search for tests of the BBN constraint on c_s derived in Section III. On the other hand, in the present approximation, for the determination of the values of $|p_e|$, $|q_e|$ and $|p_s|$ in principle the results of SBL experiments alone are sufficient.

The free parameter $|p_e|^2$ is fixed by a measurement of the SBL $\nu_\mu \rightleftharpoons \nu_e$ oscillation amplitude. With the result of the LSND experiment and the negative result of all other SBL neutrino oscillation experiments $|p_e|^2$ is approximately bounded by $0.5 \times 10^{-3} \lesssim |p_e|^2 \lesssim 10^{-2}$. If the BBN constraint on c_s is valid, then $\nu_\mu \rightarrow \nu_\tau$ transitions are significantly suppressed in SBL neutrino oscillation experiments with an oscillation amplitude of order 10^{-3} or smaller. Furthermore, Eq.(5.30) shows that the oscillation amplitude $A_{e;\tau}$ is at most close to 0.1.

In the discussion in Section III we have seen that the BBN bound $N_\nu \lesssim 3.9$ implies that $c_s \ll 10^{-2}$. In this case we have

⁶Actually, this is always possible because of unitarity, but in general the relations are very complicated.

$$B_{\mu;\mu} \simeq A_{\mu;e} \quad \text{and} \quad A_{\mu;\tau} \simeq \frac{1}{4} A_{\mu;e} A_{e;\tau}. \quad (5.32)$$

Inspecting Eq.(5.27) we note that in scheme A the quantity $1 - c_\mu$ is now of the same order of magnitude as c_e . As mentioned in the previous Section, this is particularly interesting for $\Delta m_{\text{SBL}}^2 \lesssim 0.3 \text{ eV}^2$ where the bound on $B_{\mu;\mu}$ from the ν_μ disappearance experiments is not very stringent and, consequently, in this Δm_{SBL}^2 region $B_{\mu;\mu}$ should be much smaller than the present upper experimental upper bound. In addition, also $1 - c_\tau$ is of the same order of magnitude, showing that at zeroth-order in the expansion over the small quantities c_e and c_s , the mixing matrix is given by

$$U \simeq \begin{pmatrix} 0 & v \\ w & 0 \\ w^\perp & 0 \\ 0 & v^\perp \end{pmatrix} \quad (5.33)$$

Therefore, we have

$$\begin{aligned} \nu_e &\simeq \cos \theta \nu_3 + \sin \theta \nu_4, & \nu_s &\simeq -\sin \theta \nu_3 + \cos \theta \nu_4, \\ \nu_\mu &\simeq \cos \gamma \nu_1 + \sin \gamma \nu_2, & \nu_\tau &\simeq -\sin \gamma \nu_1 + \cos \gamma \nu_2. \end{aligned} \quad (5.34)$$

Hence, the $\nu_e, \nu_s - \nu_3, \nu_4$ and $\nu_\mu, \nu_\tau - \nu_1, \nu_2$ sectors are decoupled and the oscillations of solar and atmospheric neutrinos are independent. Furthermore, since only the small mixing angle MSW solutions of the solar neutrino problem seems to be allowed by the data in the case of $\nu_e \rightarrow \nu_s$ transitions (see Refs. [31,32,16]), at zeroth-order in the expansion over the small quantities c_e, c_s and θ we have

$$\nu_e \simeq \nu_3, \quad \nu_s \simeq \nu_4. \quad (5.35)$$

Similar conclusions are valid in scheme B with c_α replaced by $1 - c_\alpha$ and $1, 2 \leftrightarrow 3, 4$.

Let us now discuss LBL neutrino oscillations. Keeping only the dominant terms we get

$$P_{\nu_\mu \rightarrow \nu_\tau}^{(\text{LBL})} \simeq 1 - P_{\nu_\mu \rightarrow \nu_\mu}^{(\text{LBL})} \simeq \sin^2(2\gamma) \sin^2(\phi/2) \quad (5.36)$$

where $\phi \simeq \Delta m_{21}^2 L/2p$ in scheme A and $\Delta m_{43}^2 L/2p$ in scheme B. This shows that there must be significant LBL $\nu_\mu \rightarrow \nu_\tau$ oscillations because of the sizeable ν_μ disappearance known from the atmospheric neutrino anomaly, which implies that $\sin^2(2\gamma)$ is large. For $\nu_\mu \rightarrow \nu_e$ and $\nu_e \rightarrow \nu_\tau$ transitions matter effects have to be taken into account. The upper bounds on these transition probabilities derived in Ref. [24] are of order 10^{-2} . If c_s is small, as follows from the BBN constraint, the ‘‘matter-stable’’ bounds on $P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}$ and $P_{\nu_e \rightarrow \nu_\tau}^{(\text{LBL})}$ derived in Ref. [24] are improved for small values of Δm_{SBL}^2 because of the inequalities

$$c_\mu, c_\tau \geq 1 - a_e^0 - c_s, \quad (5.37)$$

leading to

$$P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}, P_{\nu_e \rightarrow \nu_\tau}^{(\text{LBL})} \leq 2a_e^0(1 - a_e^0) + c_s(1 - 2a_e^0). \quad (5.38)$$

Hence, the BBN constraint on c_s imply that

$$P_{\nu_\mu \rightarrow \nu_e}^{(\text{LBL})}, P_{\nu_e \rightarrow \nu_\tau}^{(\text{LBL})} \lesssim 2a_e^0(1 - a_e^0). \quad (5.39)$$

Obviously, the observation of a violation of these inequalities in LBL neutrino oscillation experiments would imply that the BBN constraint on c_s is not valid.

VI. CONCLUSIONS

In this paper we have focused our discussion on the two four-neutrino schemes A and B (see Eq.(1.5)) which are compatible with the results of all neutrino oscillation experiments [22,23]. As shown in Ref. [23], the bound $N_\nu \lesssim 3.9$ for the effective number N_ν of light neutrinos before the onset of BBN implies a stringent upper bound on $c_s \equiv \sum_{k=1,2} |U_{sk}|^2$ in scheme A and on $1 - c_s$ in scheme B. Our limits are more stringent than those of Ref. [23] because we used the complete collision rates presented in Ref. [42]. Thus, in scheme A we have obtained $c_s \lesssim 5 \times 10^{-3}$. We have demonstrated that in scheme B the limit derives from resonant transitions due to Δm_{SBL}^2 , leading to an upper bound for $1 - c_s$ that is more stringent than the one for c_s in scheme A: $1 - c_s \lesssim 5 \times 10^{-5}$.

The validity of these limits from BBN depends to a certain extent on the results of the measurements of the primordial deuterium abundance which are controversial at the moment [27]. We have therefore emphasized the importance of terrestrial experiments to get information on the value of c_s in order to check the BBN constraints. In Section IV we have worked out lower bounds on c_s in scheme A ($1 - c_s$ in scheme B) involving the following observables in SBL experiments:

- i. the $\nu_\mu \rightarrow \nu_\tau$ oscillation amplitude $A_{\mu;\tau}$;
- ii. the oscillation amplitude $B_{\mu;\mu}$ in ν_μ disappearance experiments for $\Delta m_{\text{SBL}}^2 \lesssim 0.3 \text{ eV}^2$;
- iii. the oscillation amplitudes $B_{e;e}$ in reactor disappearance experiments and $A_{\mu;e}$ and $A_{e;\tau}$ in accelerator experiments.

To proceed further, in Section V we have introduced a parameterization of the 4×4 neutrino mixing matrix U (5.7) which is particularly suited for the schemes A and B. In this parameterization the quantity c_s is given by $c_s = |p_s|^2 + |q_s|^2$ in scheme A ($1 - c_s = |p_s|^2 + |q_s|^2$ in scheme B), where p_s and q_s are in general complex parameters in U . The parameterization (5.7) has lead us to the following observations:

- (a) The parameter $|p_s|$ can be determined in SBL $\nu_\mu \rightarrow \nu_{e,\mu,\tau}$ oscillation experiments.
- (b) For the determination of $|q_s|$ in SBL oscillation experiments it is necessary to employ a ν_τ neutrino beam and perform a disappearance experiment.
- (c) For $N_\nu \lesssim 3.9$ the SBL oscillation amplitude $A_{\mu;\tau}$ is at most of order 10^{-3} whereas the LBL oscillation amplitude must be of order one in the same channel.

As already pointed out in Ref. [23], the BBN constraint $N_\nu \lesssim 3.9$ leads to a 4-neutrino mixing picture in which, apart from small corrections of the order of the small quantities c_e and c_s , the mixing matrix U is composed by the two decoupled sectors $\nu_e, \nu_s - \nu_3, \nu_4$ and $\nu_\mu, \nu_\tau - \nu_1, \nu_2$ in scheme A ($\nu_e, \nu_s - \nu_1, \nu_2$ and $\nu_\mu, \nu_\tau - \nu_3, \nu_4$ in scheme B). Consequently, the oscillations of solar and atmospheric neutrinos are independent. The solar neutrino problem is solved with $\nu_e \rightarrow \nu_s$ oscillations governed by the mixing angle θ and the atmospheric neutrino anomaly is explained with $\nu_\mu \rightarrow \nu_\tau$ oscillations governed by the mixing angle γ (see Eq.(5.7) for the definition of these angles). Concerning the solar neutrino deficit, it was shown that a vacuum oscillation solution involving sterile neutrinos is rather disfavored by the data (see Refs. [31,32]). Therefore, the specific prediction of a small mixing angle MSW solution of the solar neutrino problem with only $\nu_e \rightarrow \nu_s$ transitions serves as an indirect check of the schemes A and B under consideration and of the BBN bound. This prediction implies a characteristic strong distortion of the ^8B ν_e spectrum and a day-night asymmetry in the neutral current event rate at SNO [58]. Experimentally, this prediction can be checked independently from solar model calculations (see Ref. [59]).

If indeed the BBN constraints on the 4-neutrino mixing matrix U are confirmed then the biggest gap in our knowledge of U , the sterile neutrino mixing, is considerably narrowed. In this paper we have shown that it is possible to test the ensuing mixing matrix to some extent in terrestrial experiments. The most striking feature in this context is the suppression of all SBL oscillation amplitudes.

FIGURES

FIG.1. Plot in the $A_{\mu;\tau}-\Delta m_{\text{SBL}}^2$ plane of the curve $4(a_\mu^0)^2$ (solid line). For $A_{\mu;\tau}$ to the right of this curve (see Eq.(4.8)) the lower bound (4.9) for c_s applies. The dashed curve representing $B_{\mu;\mu}^0$ constitutes an upper bound for $A_{\mu;\tau}$ due to the conservation of probability. The values of a_μ^0 and $B_{\mu;\mu}^0$ have been obtained from the 90% CL exclusion curves of the CDHS [36] and CCFR [37] experiments. The dash-dotted curve, dash-dot-dotted and dotted curves represent, respectively, the most recent exclusion curve presented by the CHORUS collaboration [52], the expected final sensitivity of the CHORUS [49] and NOMAD [50] experiments and the expected sensitivity of the COSMOS [51] experiment.

FIG.2. Plot in the $c_s-\Delta m_{\text{SBL}}^2$ plane of the lower limit $2a_\mu^0 - a_e^0$ for c_s that follows from the inequality (4.8). The values of a_e^0 and a_μ^0 have been obtained from the 90% CL exclusion curves of the Bugey [35], CDHS [36] and CCFR [37] experiments.

FIG.3. Plot in the $A_{\mu;\tau}-\Delta m_{\text{SBL}}^2$ plane of the upper bound $(a_e^0)^2$ (solid curve) for $A_{\mu;\tau}$ (see Eq.(4.11)) in the case of a very small c_s . The values of a_e^0 have been obtained from the 90% CL exclusion curve of the Bugey [35] experiment. The dash-dotted curve, dash-dot-dotted and dotted curves are the same as in Fig.1.
